Background: There is a limited amount of literature on the physiological cost of batting. Of the studies that have been completed, most have used protocols that are of short duration and high intensity, and it has been questioned whether this represents actual game play. Furthermore, it is difficult to study sports such as cricket due to the intermittent nature of the game. Therefore the main aim of this present study was to examine more detailed physiological responses of players batting for extended periods of play using the BATEX® protocol, previously validated by Houghton et al.[12]

Objective: To determine the physiological responses of batsmen during a simulated One Day International century.

Methods: Seventeen male batsmen from the Rhodes University Cricket Club performed a simulated batting work bout known as the BATEX® protocol. The protocol consisted of six, five overs stages, each lasting 21 minutes. Three of the stages (stages one, three and five) were low-intensity stages and the other three (stages two, four and six) were high-intensity stages. During the work bout selected physiological responses were recorded.

Results: Heart rate (124±15-159±14 beats.min⁻¹); oxygen uptake (29.3±6.1-43.4±6.3 ml.kg⁻¹.min⁻¹); energy expenditure (48.1±9.2-109.2±10.5 kJ.min⁻¹) and core temperature (37.7±0.3-38.7±0.4°C) responses all increased significantly (p<0.05) between stages one and stage six. The respiratory exchange ratio decreased significantly (p<0.05) between stages one and six. The mean heart rate (164±12 beats.min⁻¹) recorded by Vickery et al.,[11] during a simulated, eight over, match situation is further validated by the mean heart rate of 164±12 beats.min⁻¹ recorded by Vickery et al.,[11] during a simulated century batting work bout, known as the BATEX® protocol, was used. The protocol consisted of six, five over stages (21 min each) that represented certain phases of play. The study showed a mean heart rate, tympanic temperature and sweat rate of 130 beats.min⁻¹, 35.9°C and 0.9 L.h⁻¹. However, although this investigation used a long duration protocol, the main aim was not the physiological cost of batting and so the responses measured were limited and crude. Therefore the main aim of this present study was to examine more detailed physiological responses of players batting for extended periods of play using the BATEX® protocol, previously validated by Houghton et al.[12]

Conclusions: Batting is more physically demanding than originally thought, and as a result training programmes should concentrate on simulating real match play situations to improve performance and reduce the risk of injury.

Two testing sessions were required. The first testing session was used to collect basic anthropometric and demographic data and to familiarise the players with the equipment and the simulated century protocol (BATEX© protocol as described by Houghton et al.[12]). The BATEX© protocol was used as this is the only century protocol that has been validated. Equipment included a portable online metabolic system, the kbl (Cosmed®, Rome), a Polar® heart rate monitor (Kempele, Finland) and a CoreTemp® (HQInc., United States of America) monitoring system. These were used to measure oxygen consumption (VO2), respiratory exchange ratio (RER), heart rate (HR) and core temperature (Tc) and the simulated century protocol (BATEX© protocol as described by Houghton et al.[12]).

The BATEX© protocol was used as this is an injury, after which they padded up in cricket protocol as described by Houghton et al.[12]).

After the experimental session was completed, the equipment was removed from the players and they were required to partake in a cool-down session (approximately ten minutes), which included a jog and more cricket-specific stretches.

**Statistical analysis**

All statistical analyses were performed using STATISTICA 10 software. Descriptive measures of physiological, performance and perceptual data included mean values and standard deviations. The level of significance was set at p<0.05. Effect size characterised the magnitude of difference between the various stages. The criteria for interpreting effect sizes were: <0.2 trivial, 0.2-0.6 small, 0.6-1.2 moderate, 1.2-2.0 large and >2.0 very large.[13] A one-way analysis of variance was used to compare differences between stages at different intensity levels over time. Tukey’s post hoc analyses identified specific areas of differences.

**Results**

Significant differences were observed for all measures between stage one and stage 6 (Table 1).

- Heart rate responses increased significantly (p<0.05) from stage one to stage six (124±15 to 159±14 beats.min⁻¹) with a mean heart rate of 144±15 beats.min⁻¹. A large effect size (ES) was observed between stages one and two (ES=1.60) and a moderate effect size between stages one and five (ES=0.55).

Energy expenditure responses increased significantly (p<0.05) from stage one to stage six (48.1±9.2 to 70.7±10.5 kJ.min⁻¹). A mean energy expenditure of 59.8±9.6 kJ.min⁻¹ was recorded. Large magnitude changes were observed between all stages (ES=1.58, 1.32, 1.79, 1.41) except between stages four and five where a moderate change was observed (ES = 1.15).

Significant increases (p<0.05) in core temperature were observed between stage one and stage six (37.7±0.3 to 38.7±0.4°C). The only large effect size was observed between stages one and two (ES=1.40). Mean core temperature was 38.3±0.4°C.

**Discussion**

The main finding of this study was that batting for extended periods, such as during the BATEX© protocol, significantly influences the fatigue profile experienced by a batsman, particularly when batting in a high intensity manner.
which is exacerbated by batting in the heat. This was a result of both the intensity and duration of the work bout.

Responses in this study were similar to those recorded by both King[6] and Christie et al.[4] who found mean heart rate responses of 145 and 138 beats.min⁻¹ respectively. Both studies used short duration, high-intensity work bouts where batsmen ran a double shuttle every second delivery. This suggests that batsmen regulate intensity of effort dependent on duration so that cardiovascular load remains stable. However, this must be seen within the context of the study designs which did not take into consideration aspects of game, player and competition dynamics to name a few factors which may impact heart rate responses. Pote and Christie[40] found higher heart rate responses in their study (140-168 beats.min⁻¹) this was to be expected as, although the protocol was short in duration, players were required to sprint every ball, rather than every second ball. In contrast, a longer duration protocol used by Houghton et al.[12] reported lower heart rate responses than seen in this study. This can be explained by the calibre of the player. Houghton et al.[12] used professional players, while the players in this study were non-professional batsmen, although player ages for both studies were similar. Of note, however, is that the responses in this study are comparable to data obtained during real match play even though the players were not exposed to actual game dynamics, such as scoreboard pressure and importance of the match (exhibition vs. World Cup match).[9,10] This was not the case though when compared to Gore et al.[4], who also looked at real match play data (mean of 144±15 beats.min⁻¹); however, this was to be expected as the game of cricket has changed to a large extent since 1993.

An interesting finding was the effect of both duration and intensity on heart rate responses. Previous batting studies have shown that duration had no impact on cardiovascular responses.[14] This was not the case in this study as there was a significant (p<0.05) increase in heart rate between stages one and six (124-159 beats.min⁻¹) as well as a significant (p<0.05) increase between stages two and six (148-159 beats.min⁻¹), thus showing the effect of duration on changing physiological responses.

Mean oxygen consumption (36.7±6.5 ml.kg.min⁻¹) was considerably higher than shown in previous cricketing studies (Christie et al.[4]: 26.7 ml.kg.min⁻¹; Pote and Christie[40]: 26.9 ml.kg.min⁻¹). This could be because those studies used shorter protocols and because in this study, VO₂ rose significantly (p<0.05) between stages one and two (29.3-38.7 ml.kg.min⁻¹) and then remained high throughout the rest of the protocol. This indicates that players may not have recovered sufficiently in the low-intensity stages before starting the high-intensity stages. The duration of the protocol and the intensity of the different stages also affected VO₂ responses as shown by the large effect sizes (ES=1.45, 1.62 and 1.24, between stages one and two, three and four and five respectively).

Mean RER during the protocol (0.90±0.18) was lower than the only other study to report on this response during batting (Christie et al.[4]: 1.05), as more carbon dioxide was produced due to the high intensity of the shorter protocol, therefore resulting in an increased RER. At the start of the protocol, players were utilising mainly carbohydrates as an energy source, but as the protocol approached the drinks break there was a shift in substrate utilisation, due to the increase in exercise duration, indicating reduced reliance on carbohydrates.[14] The slight rise in RER after the drinks break could be attributed to the ingestion of an Energade sports energy drink (645 kJ; 39 g CHO), which could have resulted in higher carbohydrate utilisation from the ingested glucose. RER then decreased for the remainder of the protocol indicating a greater reliance on fats as an energy source, which was to be expected. Important to acknowledge, however, is that RER during intense exercise may not be a reliable indicator of substrate use, although it could be argued that in this study, over time, intensity of effort was moderate.

The mean energy cost (59.8±9.6 kJ.min⁻¹) observed in this study was substantially higher than that proposed by Fletcher[5] in 1955. However, this must be seen within the context of the changing nature of the game, specifically with respect to higher batting scores and individual runs scored per innings. When compared to other cricketing studies (Christie et al.[4]: 42.3 kJ.min⁻¹; Pote and Christie[4]: 46.4 kJ.min⁻¹), the responses shown in this study are higher. This was to be expected as batsmen batted for a longer time, ran a higher number of runs and performed the protocol at different intensities. This emphasises the importance of measuring the impact that prolonged batting has on players. An understanding of these factors will influence the design of training programmes which has important performance implications for these players. Batsmen were also required to ‘touch and turn’ at the non-strikers end when running a single as if looking for another run. This may have affected the energy cost recorded, as research has shown that the deceleration, turning at the crease and reacceleration have an impact on energy cost.[8] Furthermore, because other physiological responses were not affected by this occurrence, it means that this extra energy cost may be the result of changes in the player’s muscle force, producing capabilities required when turning for another run.[8]

Mean core temperature (38.3±0.4°C) was higher than in previous cricket studies, but the previous studies used field-based conditions, skill, rectal and forehead temperature. It has also been suggested that the ingestible pill is more accurate than these measuring techniques.[6,7,12,16] When temperatures were compared to the only other long duration study of Houghton et al.[12] who reported a 0.3°C rise in temperature over the 30 over protocol, this present study showed a rise of 1.1°C in the same time period. This may be due to the different testing conditions (laboratory- vs. field-based testing) or the difference in measuring techniques (tympanic vs. ingestible pill, the latter of which is more accurate). The rise in core temperature was probably due to the active muscles requiring additional blood, thus compromising blood flow to the skin and therefore limiting heat transfer to the environment.[27] Other factors that may have affected core temperature include glycogen depletion, hypohydration, and the accumulation of potassium in the interstitium of the muscle.[18] However, the fact that core temperature did not reach critical levels suggests that players are able to regulate intensity of effort to prevent excessive rises in core temperature. Future studies should consider measuring sprint time changes in order to establish whether batsmen are slowing down over time; something which would impact core temperature changes.

Limitations
This study must be seen within the context of its limitations. The primary limitation is the fact that this was a laboratory-based, simulation protocol and was therefore not able to take into account all aspects of a cricket game, such as varying environmental conditions. Furthermore, the impact that the crowd has on a batsmen during a normal ODI could not be replicated, although verbal encouragement was given to batsmen when necessary.
Conclusion

The current study is the only investigation, to date, to observe a multitude of physiological responses during extended periods of batting. Results show that batting is substantially more physiologically taxing than originally thought. This highlights the importance of the need for training programmes that simulate real match situations, specifically for batsmen who are required to bat for long periods of time. The type of training done by players needs to closely mimic the demands that players are faced with in real match play. Furthermore, a standardised battery of tests needs to be developed that can be used for not only testing the physical fitness characteristics of batsmen but also for improving training status. Consideration could then be given to the concept of specificity and current demands placed on top-order batsmen.
